Soil microbial communities in the Arctic, one of the most rapidly warming regions on Earth, play an important role in a range of ecological processes. This report describes initial studies of natural soil bacterial diversity at a High Arctic site on Svalbard, as part of a long-term field environmental manipulation study. The impact of increased soil temperature and water availability on soil microbial communities was investigated. The manipulation experiment, using open-top chambers, was installed in late summer 2014, and the soils were sampled soon after snow melt in July 2015. High throughput sequencing of 16S rRNA genes showed relatively uniform diversity across the study area and revealed no significant initial effect of treatments on bacterial communities over the first 10-month autumn–winter–spring manipulation period.

Keywords: Arctic soil bacterial diversity, high throughput sequencing, open top chambers, Svalbard.

Introduction

GLOBAL climate change is predicted to have a greater impact at high latitudes, particularly in the Arctic, which is already warming and is expected to continue warming more quickly than lower latitude regions due to a phenomenon known as polar amplification^{1,2}. Climate models predict warmer Arctic winters, which could both increase and decrease local snow cover and change the frequencies of freeze-thaw cycles³. Together, these changes may lead to both an increase and decrease in water availability to microbiota, owing to the thawing of ice and greater drainage respectively⁴. Soil microorganisms are fundamental to major global biogeochemical cycles⁵, particularly in polar regions⁶. The objective of the present study was to analyse, using a high throughput sequencing approach, the initial effects of open-top chamber (OTC) warming and water input on Arctic soil bacteria in a representative tundra habitat near Ny-Ålesund, Svalbard.

Data presented here were obtained after a ~10-month autumn–winter–spring period following OTC deployment.

Experimental design

The experiment was established on 11 and 12 September 2014 at Kvadrehukken on the Brøggerhalvøya Peninsula, Svalbard (78°58.002'N, 11°28.446'E). Forty-eight plots in three blocks were established in an extensive area of periglacial patterned ground (Figure 1). Warming by OTCs (ITEX chambers⁷) and water amendment (1 L of deionized water) were applied in factorial combination to frost boils (Table 1). Soil samples (*c.* 1 g) were collected from each plot on 1 July 2015 and brought to the UK Arctic Research Station at Ny-Ålesund within 3 h to be frozen at -20°C. The frozen soils were subsequently transported to the University of Malaya, Kuala Lumpur, where they were stored at -20°C until further use.

High throughput sequencing and statistical analysis

Total genomic DNA was extracted from each soil sample using the MoBioPowerSoil DNA extraction kit (MOBIO

Laboratories, CA, USA) according to the manufacturer's instructions. The V3 and V4 hypervariable regions of bacterial 16S rRNA genes were amplified by PCR⁸. Each reaction mixture (25 µl) contained 12.5 µl of 2X KAPA HiFi HotStart ReadyMix (Kapa Biosystem, MA, USA), 10 µM of each primer, 12 ng of genomic DNA and 10.5 µl of ultrapure water with conditions set according to the manufacturer's instructions. Generation of a sequence library was conducted using the MiSeq System

(Illumina Inc., CA, USA) at Monash University, Malaysia Genomics Facility, following the 2 × 250-bp paired-end protocol.

The generated demultiplexed sequences were filtered according to base quality ($q = 20$) using CLC Genomic Workbench 8.5. Assembled sequences were processed with QIIME 1.8.0 (ref. 9) with Greengenes¹⁰ as a resource for taxonomic (OTU) assignment. They were then normalized via random sub-sampling at 1642 reads per

sample for alpha-diversity and beta-diversity calculations. UniFrac distances, both weighted and unweighted, were computed among all the samples to generate principal coordinate analysis (PCoA) plots. To test for significant differences in the mean PC1 scores of both the weighted and unweighted UniFrac distances between blocks and treatments, one-way ANOVA was conducted with a *post hoc* comparison using Tukey's Honestly Significant Difference (HSD) test (IBM SPSS Windows version 19.0, NY, USA).

Results and discussion

Bacterial community composition at the OTU level was unaffected by either the OTC warming treatment or water amendment at an early stage of the field manipulation experiment (Figure 2). The community composition was also spatially uniform across the three experimental blocks in the field (Figure 3). ANOVA with Tukey's HSD showed that no significant differences were present in the weighted or unweighted UniFrac PC1 scores between the different treatments in each of the three blocks

individually, or between the three blocks (data not shown). No differences were apparent in the patterns of predominant bacterial phyla in soil from the different treatments and experimental blocks. The most abundant bacterial phyla were the Proteobacteria, Actinobacteria, Acidobacteria, Planctomycetes, Cyanobacteria, Chloroflexi, Bacteroidetes, Cyanobacteria and Verrucomicrobia (Figure 3). These represent previous Arctic soil records: for instance Acidobacteria, Bacteroidetes and Proteobacteria were all found to be frequent in permafrost of north-east Greenland¹¹.

Our results demonstrate that 10 months of warming with OTCs did not influence the bacterial community composition of the studied soil, or the relative abundance of the predominant phyla. An absence of treatment effects, during a period in which the mean soil temperatures in control and chambered plots were -1.81°C and -1.19°C respectively, was not surprising as treatment effects of OTCs are usually restricted to the summer months^{12,13}.

Other studies also show that Arctic soil microbial communities respond very slowly to warming treatments. Experiments using OTCs to warm High Arctic soils have shown significant changes in community structure and

genotype richness of nitrous oxide-reducing and atmospheric nitrogen-fixing bacterial genes in soil, but only after 13 years. However, the most pronounced effects were recorded in wet meadows, suggesting the importance of water in determining microbial responses to warming treatments¹⁴. Such water-dependent warming effects have also been observed in fungal community responses to warming treatments of Arctic soils¹⁵.

In conclusion, this initial study found no immediate effects of warming and water amendment on soil bacterial communities of Svalbard. Bacterial taxa variation between blocks and the number of OTUs present in soil was found to be negligible, indicating that this is a suitable experiment in which to detect changes in bacterial community composition in response to environmental manipulations in future.

The metagenome sequence data from this study have been deposited in NCBI under the Sequence Read Archive (SRA) database with accession number SRP105234 and BioProject number PRJNA356212.
